Comparison Inequalities and Fastest-Mixing Markov Chains

Jim Fill, Johns Hopkins University

We introduce a new partial order on the class of stochastically monotone Markov kernels having a given stationary distribution π on a given finite partially ordered state space $\mathcal{X}$. When $K \preceq L$ in this partial order we say that K and L satisfy a *comparison inequality*. We establish that if $K_1, \dots, K_t$ and $L_1, \dots, L_t$ are reversible and $K_s \preceq L_s$ for $s = 1, \dots, t$, then $K_1 \cdots K_t \preceq L_1 \cdots L_t$. In particular, in the time-homogeneous case we have $K^t \preceq L^t$ for every t if K and L are reversible and $K \preceq L$, and using this we show that (for suitable common initial distributions) the Markov chain Y with kernel K mixes faster than the chain Z with kernel L, in the strong sense that *at every time* t the discrepancy—measured by total variation distance or separation or L^2-distance—between the law of Y_t and π is smaller than that between the law of Z_t and π.

Using comparison inequalities together with specialized arguments to remove the stochastic monotonicity restriction, we answer a question of Persi Diaconis by showing that, among all symmetric birth-and-death kernels on the path $\mathcal{X} = \{0, \dots, n\}$, the one (we call it the *uniform chain*) that produces fastest convergence from initial state 0 to the uniform distribution has transition probability $1/2$ in each direction along each edge of the path, with holding probability $1/2$ at each endpoint.

We also use comparison inequalities

(i) to identify, when π is a given log-concave distribution on the path, the fastest-mixing stochastically monotone birth-and-death chain started at 0, and

(ii) to recover and extend a result of Peres and Winkler that extra updates do not delay mixing for monotone spin systems.

Among the fastest-mixing chains in (i), we show that the chain for uniform π is slowest in the sense of maximizing separation at every time.
